Company Name AstraZeneca Eli Lilly Iroko Bayer Sanofi Aventis Rafa Laboratories Relationship honoraria, consultant honoraria, consultant Honorarium consultant consultant consultant

A QUIZ TO THE AUDIENCE:

- A 52 y.o. male is admitted for a first inferior STEMI.
- Emergency coronary angiography reveals a totally occluded 1st marginal branch. There are no other lesions.
- Primary PCI is performed with a good result. Pain to balloon time is 150 min.

A QUIZ TO THE AUDIENCE:

- Follow up EKG shows complete ST resolution
- LV function is preserved with posterior hypokinesis.
- The patient is given aspirin, prasugrel and a statin.
- Will his short or long term prognosis be improved by beta blockade?

HOW DO BETA BLOCKERS IMPROVE OUTCOME IN CAD?

- Attenuation of ischemia through reduced demand
- Attenuation of ventricular remodeling
- Prevention of lethal arrhythmias and sudden death

DO BETA BLOCKERS IMPROVE OUTCOME POST MI?

- In patients with residual ischemia possibly
 - Most patients currently discharged w/o significant residual ischemia
- In patients with LV dysfunction definitely
- In patients with preserved EF?
 - Remodeling and heart failure not an issue
 - Risk of lethal arrhythmias extremely small.

SUBGROUPS OF AMI PATIENTS

- NSTEMI
- MI with LV dysfunction
- STEMI routine, in hospital phase
- STEMI routine, long term

Efficacy of Nifedipine and Metoprolol in the Early Treatment of Unstable Angina in the Coronary Care Unit: Findings from the Holland Interuniversity Nifedipine/Metoprolol Trial (HINT)*

- Study conducted 1981-1984
- 338 patients with USAP randomized to metoprolol 100 mg*2/d, nifedipine 10 mg*6/d, both or neither.
- Primary outcome recurr. ischemia/MI @ 48 h
- 25% had MI within a week.

Efficacy of Nifedipine and Metoprolol in the Early Treatment of Unstable Angina in the Coronary Care Unit: Findings from the Holland Interuniversity Nifedipine/Metoprolol Trial (HINT)*

- Other medications: antiplatelet: 3%, heparin/coumadin: 67%, nitrates: 67%
- Nifedipine worse outcome than placebo
- Metoprolol better outcome than placebo
- Nothing significant!
- Conclusion: Nifedipine monotherapy "probably harmful", metoprolol "probably useful"

Lubsen et al, Am J Cardiol 1987;60:18A

TRIAL OF HEPARIN VERSUS ATENOLOL IN PREVENTION OF MYOCARDIAL INFARCTION IN INTERMEDIATE CORONARY SYNDROME

ANNE M. TELFORD

CHARLES WILSON

Cardiac Unit, Waveney Hospital, Ballymena, Co. Antrim, Northern Ireland

- Study conducted 1977-1980
- 214 patients with USAP/subendocardial MI randomized to heparin/placebo and atenolol/placebo.

The results of this study suggest that intravenous heparin therapy was highly beneficial in the prevention of myocardial infarction among patients presenting with symptoms consistent with the intermediate coronary syndrome. The beta-adrenergic blocking drug, atenolol, on the other hand, had no demonstrable effect. The benefit conferred by heparin was maintained on follow-up.

Myocardial Infarction: Is there a Class Effect for β-blockers?

Total Mortality Reduction after Myocardial Infarction

Freemantle N, et al. BMJ 1999;318:1730-7.

STUDIES SHOWING BENEFIT POST STEMI

- Mostly from the 70's and 80's.
- Before:
 - Reperfusion therapy
 - Aspirin
 - ADP receptor antagonists
 - Statins
 - ICD's
 - PCI
- In the absence of reperfusion the prevalence of LV dysfunction was much higher

REDUCTION OF INFARCT SIZE WITH THE EARLY USE OF TIMOLOL IN ACUTE MYOCARDIAL INFARCTION

THE INTERNATIONAL COLLABORATIVE STUDY GROUP

Abstract One hundred forty-four patients admitted to the hospital within four hours after onset of symptoms of myocardial infarction were randomly assigned to either intravenous timolol treatment or to placebo. Timolol was given intravenously for the first 24 hours and orally thereafter for the duration of hospitalization. Infarct evolution was assessed by continuous vectorcardiography and creatine kinase release. The timolol group had reduced myocardial ischemia and infarct size as measured by an accelerated reduction of ST-vector magnitude, a significant reduction of maximal cumulative creatine kinase

release (29.5 per cent), and significantly smaller changes in QRS-vector variables (20 to 25 per cent). Furthermore, the predicted creatine kinase release and maximal QRS-vector change for a given initial ST-vector magnitude was significantly reduced in the timolol group. Timolol was also associated with significant reductions in pain and need for analgesics and was well tolerated overall.

This study supports the use of intravenous timolol in the early phase of suspected myocardial infarction to limit infarct size. (N Engl J Med 1984; 310:9-15.)

Law of diminishing returns

Law of diminishing returns: output will ultimately increase by progressively smaller amounts when the use of a variable input increases while other inputs are held constant.

Law of Diminishing Returns

INVESTMENT: TIME, ENERGY, MONEY ETC.

THE LAW OF DIMINISHING RETURNS

- The absolute benefit of a medical intervention, and therefore the NNT and the ability to demonstrate benefit, vary directly with baseline risk, which in a randomized trial can be assessed by event rate in the placebo group.
- Each successive intervention that reduces RELATIVE risk will progressively reduce the ABSOLUTE benefit of further interventions
- As the baseline risk of a population decreases, interventions that do not explain this decline (at least not largely) should be reexamined.

The Law of Diminishing Returns in Clinical Medicine: How Much Risk Reduction is Enough?

James W. Mold, MD, MPH, Robert M. Hamm, PhD, and Laine H. McCarthy, MLIS

The law of diminishing returns, first described by economists to explain why, beyond a certain point, additional inputs produce smaller and smaller outputs, offers insight into many situations encountered in clinical medicine. For example, when the risk of an adverse event can be reduced in several different ways, the impact of each intervention can generally be shown mathematically to be reduced by the previous ones. The diminishing value of successive interventions is further reduced by adverse consequences (eg, drug-drug, drug-disease, and drug-nutrient interactions), as well as by the total expenditures of time, energy, and resources, which increase with each additional intervention. It is therefore important to try to prioritize interventions based on patient-centered goals and the relative impact and acceptability of the interventions. We believe that this has implications for clinical practice, research, and policy. (J Am Board Fam Med 2010;23: 371–375.)

Can the risk of low risk patients be further reduced?

- 1 year mortality among low risk patients in HORIZONS : 0.8%.
- If beta blockers reduce mortality by 15% in these patients (questionable!) the mortality would be 0.68%.
- Absolute risk reduction: 0.12%
- NNT: 833

β-Blocker Use and Clinical Outcomes in Stable Outpatients With and Without **Coronary Artery Disease**

Sripal Bangalore, MD, MHA Ph. Gabriel Steg, MD Prakash Deedwania, MD Kevin Crowley, MS Kim A. Eagle, MD Shinva Goto, MD, PhD E. Magnus Ohman, MD Christopher P. Cannon, MD Sidney C. Smith Jr, MD Uwe Zevmer, MD Elaine B. Hoffman, PhD Franz H. Messerli, MD Deepak L. Bhatt, MD, MPH for the REACH Registry Investigators REATMENT WITH β-BLOCKERS remains the standard of care for patients with coronary artery

disease (CAD), especially when they have had a myocardial infarction (MI).^{1,2} The evidence is derived from relatively old post-MI studies, most of which antedate modern reperfusion or medical therapy, and from heart failure trials, but has been widely extrapolated to patients with CAD and even to patients at high risk for but without established CAD. It is not known if these extrapolations are justified. Moreover, the long-term efficacy of these agents in patients treated with contemporary medical therapies is not known, even in patients with prior MI.

B-Blockers are not without adverse JAMA 2012:308(13):1340-1349

Context β-Blockers remain the standard of care after a myocardial infarction (MI). However, the benefit of β -blocker use in patients with coronary artery disease (CAD) but no history of MI, those with a remote history of MI, and those with only risk factors for CAD is unclear.

Objective To assess the association of β -blocker use with cardiovascular events in stable patients with a prior history of MI, in those with CAD but no history of MI, and in those with only risk factors for CAD.

Design, Setting, and Patients Longitudinal, observational study of patients in the Reduction of Atherothrombosis for Continued Health (REACH) registry who were divided into 3 cohorts: known prior MI (n = 14 043), known CAD without MI (n = 12 012), or those with CAD risk factors only (n = 18653). Propensity score matching was used for the primary analyses. The last follow-up data collection was April 2009.

Main Outcome Measures The primary outcome was a composite of cardiovascular death, nonfatal MI, or nonfatal stroke. The secondary outcome was the primary outcome plus hospitalization for atherothrombotic events or a revascularization procedure.

Results Among the 44708 patients, 21860 were included in the propensity scorematched analysis. With a median follow-up of 44 months (interguartile range, 35-45 months), event rates were not significantly different in patients with β -blocker use compared with those without β -blocker use for any of the outcomes tested, even in the prior MI cohort (489 [16.93%] vs 532 [18.60%], respectively; hazard ratio [HR], 0.90 [95% CI, 0.79-1.03]; P = .14). In the CAD without MI cohort, the associated event rates were not significantly different in those with β -blocker use for the primary outcome (391 [12.94%] vs without β -blocker use (405 [13.55%]) (HR, 0.92 [95% Cl, 0.79-1.08]; P=.31), with higher rates for the secondary outcome (1101 [30.59%] vs 1002 [27.84%]; odds ratio [OR], 1.14 [95% CI, 1.03-1.27]; P=.01) and for the tertiary outcome of hospitalization (870 [24.17%] vs 773 [21.48%]; OR, 1.17 [95% Cl, 1.04-1.30]; P=.01). In the cohort with CAD risk factors only, the event rates were higher for the primary outcome with β -blocker use (467 [14.22%]) vs without β -blocker use (403 [12.11%]) (HR, 1.18 [95% Cl, 1.02-1.36]; P=.02), for the secondary outcome (870 [22.01%] vs 797 [20.17%]; OR, 1.12 [95% CI, 1.00-1.24]; P=.04) but not for the tertiary outcomes of MI (89 [2.82%] vs 68 [2.00%]; HR, 1.36 [95% CI, 0.97-1.90]; P=.08) and stroke (210 [6.55%] vs 168 [5.12%]; HR, 1.22 [95% CI, 0.99-1.52]; P=.06). However, in those with recent MI (≤1 year), β -blocker use was associated with a lower incidence of the secondary outcome (OR, 0.77 [95% Cl, 0.64-0.92]).

Conclusion In this observational study of patients with either CAD risk factors only, known prior MI, or known CAD without MI, the use of β -blockers was not associated with a lower risk of composite cardiovascular events.

EXAMPLE 1: ACE-I IN PATIENTS WITH PRESERVED LV FUNCTION

- The HOPE and EUROPA trials showed significant benefit of ACE inhibitors in patients at risk who did not have significant LV dysfunction.
- The PEACE trial could not confirm these findings.
- All 3 trials had similar designs

Cumulative Incidence of the Primary End Point, According to Treatment Group

Kaplan–Meier diagrams (P values are those of the univariate analysis; see Table 4).

WHY THE DIFFERENCE?

	GISSI-P	OMEGA
Statins	29%	94%
Control event rate	15.8/1000	8.9/1000
Sudden death	10.4/1000	3.7/1000

CONCLUSIONS

- NSTEMI: No evidence that beta blockers are superior to placebo, particularly in the absence of LV dysfunction
- STEMI with LV dysfunction beta blockers should be given based on CAPRICORN and older data which include many patients with LV dysfunction.

CONCLUSIONS

- STEMI with preserved LV function beta blockers never shown to be beneficial in such patients. The possible absolute benefit with contemporary management is extremely small, if any.
- ACE inhibitors: definitely indicated in the presence of LV dysfunction. With preserved LV: tailor therapy according to individual risk

Routine therapies in the acute, subacute and long term phase of STEMI

Dral treatment with beta-blockers should be considered during hospital stay and continued thereafter in all STEMI patients without contraindications.	lla	В
Oral treatment with beta-blockers is indicated in patients with heart failure or LV dysfunction.	1	Α
ntravenous beta-blockers must be avoided in patients with hypotension or heart failure.	ш	В
ntravenous beta-blockers should be considered at the time of presentation in patients without contraindications, with high blood pressure, tachycardia and no signs of heart failure.	lla	в
A fasting lipid profile must be obtained in all STEMI patients, as soon as possible after presentation.	1	С
t is recommended to initiate or continue high dose statins early after admission in all STEMI patients without contraindication or history of intolerance, regardless of initial cholesterol values.	I.	A
Reassessment of LDL-cholesterol should be considered after 4–6 weeks to ensure that a target value of ≤1.8 mmol/L [70 mg/dL] has been reached.	lla	с
/erapamil may be considered for secondary prevention in patients with absolute contraindications to beta-blockers and no heart failure.	ПР	В
ACE inhibitors are indicated starting within the first 24 h of STEMI in patients with evidence of heart failure, LV systolic dysfunction, diabetes or an anterior infarct.	1	А
An ARB, preferably valsartan, is an alternative to ACE inhibitors in patients with heart failure or LV systolic dysfunction, particularly those who are intolerant to ACE inhibitors.	I.	В
ACE inhibitors should be considered in all patients in the absence of contraindications.	lla	Α
Aldosterone antagonists, e.g. eplerenone, are indicated in patients with an ejection fraction ≤40% and heart failure or diabetes, provided no renal failure or hyperkalaemia.	1	В

A QUIZ TO THE AUDIENCE:

- 52 y.o. male, inferior STEMI.
- Successful primary PCI, good reperfusion.
- Single vessel disease, preserved LV function.
- Aspirin, prasugrel, statin
- If you think data obtained 30 years ago in the absence of all the above modalities are relevant – you should give a beta blocker
